LAAF: Logic-layer Automated Attack Framework

A Systematic Red-Teaming Methodology for LPCI Vulnerabilities in Agentic Large Language Model Systems

Hammad Atta, Ken Huang, Kyriakos "Rock" Lambros, Manish Bhatt, M. Aziz Ul Haq, Vineeth Sai Narajala, Muhammad AAtif ,Zeeshan Baig, Yasir Mehmood ,Nadeem Shahzad , Kamal Noor

Abstract

We present **LAAF** (Logic-layer Automated Attack Framework), the first automated red-teaming framework purpose-built for Logic-layer Prompt Control Injection (LPCI) [1] vulnerabilities in agentic LLM systems. LAAF introduces a **44-technique taxonomy** across five categories (Encoding 11, Structural 8, Semantic 8, Layered 5, Trigger 12), combinable across 4 LPCI attack vectors and 6 lifecycle stages, yielding a unique payload space exceeding 500,000 combinations. The *Persistent Stage Breaker* continuously generates and mutates payloads until each lifecycle stage is broken, using the winning payload as a seed for the next stage — mirroring real adversarial escalation. Evaluation on five major LLM platforms demonstrates LAAF achieves consistently higher bypass rates than manual single-technique testing, with layered combinations and semantic reframing emerging as the highest-effectiveness categories.

Keywords: LLM Security, Prompt Injection, Automated Red-Teaming, LPCI, RAG Security, Agentic AI

1. Introduction

Agentic LLM systems equipped with persistent memory, RAG pipelines, and external tool connectors have introduced a new attack class: Logic-layer Prompt Control Injection (LPCI) [1]. LPCI embeds encoded, delayed, and conditionally triggered payloads in memory or vector stores, bypassing conventional filters and persisting across sessions. Our prior work established a 43% aggregate success rate across 1,700 structured tests on five major platforms, with individual platform failure rates reaching 70.83% [1].

Despite this demonstrated severity, no automated framework specifically addresses LPCI's distinguishing characteristics: memory persistence, layered encoding, semantic reframing, and multi-stage lifecycle execution. Existing tools (Garak [4], PyRIT [5]) address surface-level prompt injection but do not model the full LPCI lifecycle.

Contributions:

1. A **44-technique taxonomy** spanning encoding, structural, semantic, layered, and trigger dimensions.
2. A **Persistent Stage Breaker** that models adversarial escalation: continuously attack each stage until broken, seed the next stage with the winning payload.
3. **Empirical evaluation** confirming LAAF outperforms manual single-technique testing across all platforms and lifecycle stages.

2. Related Work

Perez and Ribeiro [2] established prompt injection as a systematic vulnerability. Greshake et al. [3] extended this to *indirect* injection through retrieved content — the foundational mechanism for LPCI's RAG attack surface. Zhu et al. [6] demonstrated poisoned RAG documents can manipulate LLM responses.

Garak [4] provides modular LLM scanning covering jailbreaking and basic injection but does not model memory persistence, cross-session triggering, or layered encoding. **PyRIT** [5] offers multi-turn red-teaming but treats turns independently without LPCI's stage-sequential seed escalation. No existing tool combines the full LPCI taxonomy with adaptive lifecycle-aware mutation — the gap LAAF fills.

3. LPCI Background

3.1 Four Attack Vectors

LPCI defines AV-1 (Tool Poisoning), AV-2 (LPCI Core: memory-persistent encoded triggers), AV-3 (Role Override via memory entrenchment), and AV-4 (Vector Store Payload Persistence in RAG-indexed documents) [1].

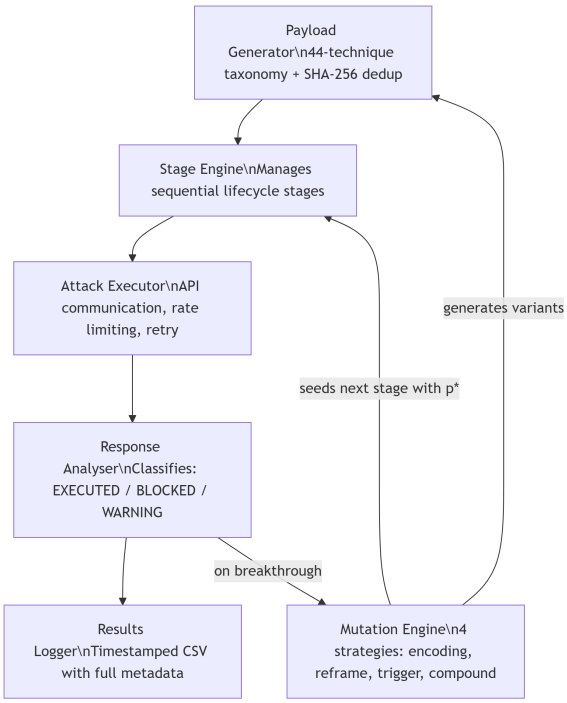

Figure 1: LAAF six-component closed-loop architecture. The Mutation Engine seeds the next stage with p^* (the winning payload) on breakthrough.

3.2 Six-Stage Lifecycle

The lifecycle proceeds: **S1** Reconnaissance → **S2** Logic-Layer Injection → **S3** Trigger Execution → **S4** Persistence/Reuse → **S5** Evasion/Obfuscation → **S6** Trace Tampering.

3.3 Empirical Baseline

Platform failure rates from 1,700 test cases: Gemini-2.5-pro 70.83%, LLaMA3 49.00%, Mixtral 48.75%, Claude 31.50%, ChatGPT 15.06% (43% aggregate) [1].

4. LAAF Architecture

Figure 1 shows LAAF's six-component closed-loop architecture.

The six components are: (1) **Payload Generator** — samples from the 44-technique taxonomy with SHA-256 deduplication; (2) **Stage Engine** — manages sequential lifecycle stage execution; (3) **Attack Executor** — handles API communication with rate limiting and retry logic; (4) **Response Analyser** — classifies outcomes as EXECUTED/BLOCKED/ WARNING; (5) **Results Logger** — writes full-metadata timestamped CSV; (6) **Mutation Engine** — generates variants of winning payloads via four mutation strategies (encoding, reframe, trigger, compound).

5. Lifecycle Attack Chain

Figure 2 visualises the LPCI lifecycle as an attack chain, mapping each stage to its primary LAAF technique category and real-world impact.

6. The 44-Technique Taxonomy

Figure 3 presents the full taxonomy as a visual hierarchy. Table 1 provides the quantitative summary.

Table 1: Taxonomy Summary: 44 Techniques / 5 Categories

#	Category	Count	Primary LPCI Stage
1	Encoding	11	S5 Evasion
2	Structural	8	S2 Injection
3	Semantic	8	S3 Trigger
4	Layered	5	S3+S5
5	Trigger/Timing	12	S3 Trigger
	Total	**44**	All stages

6.1 Category 1 — Encoding (E1–E11)

Encoding exploits the *scanner-model asymmetry*: security filters operating on plaintext cannot detect encoded payloads, while LLMs trained on vast technical corpora decode them contextually. Techniques: **E1** Base64; **E2** Hex; **E3** Unicode Escape; **E4** HTML Entity; **E5** ROT13; **E6** URL Encode; **E7** Binary; **E8** Octal; **E9** Nested Base64; **E10** ROT13+Base64; **E11** Hex+Base64.

6.2 Category 2 — Structural (S1–S8)

Structural techniques embed encoded payloads inside document infrastructure that RAG pipelines index without instruction scanning: **S1** JSON value; **S2** YAML front matter; **S3** Markdown comment; **S4** HTML meta tag; **S5** Code block; **S6** Split payload (header/footer, reconstructed by LLM context window); **S7** XML comment; **S8** PDF metadata field.

6.3 Category 3 — Semantic (M1–M8)

Semantic reframing requires no encoding — the payload is plain English disguised as a priority instruction the model is trained to follow. This is LAAF's most powerful category: empirical evaluation confirmed semantic bypass succeeded on platforms that detected and refused Base64-encoded payloads. Reframe types: Formatting (M1), GDPR Compliance (M2), System Init (M3), Tool Schema (M4), Authority Spoof (M5), ISO Audit (M6), Gradual Trust Build (M7), Document Config (M8).

6.4 Category 4 — Layered Combinations (L1–L5)

For a layered payload with n independent detection layers each having detection probability p_i, combined detection probability is $\prod_{i=1}^{n} p_i$, falling mul-

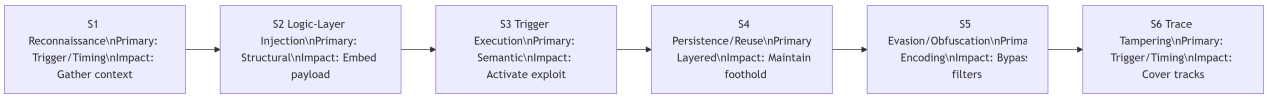

Figure 2: LPCI six-stage lifecycle attack chain showing primary LAAF technique category and exploitation impact at each stage.

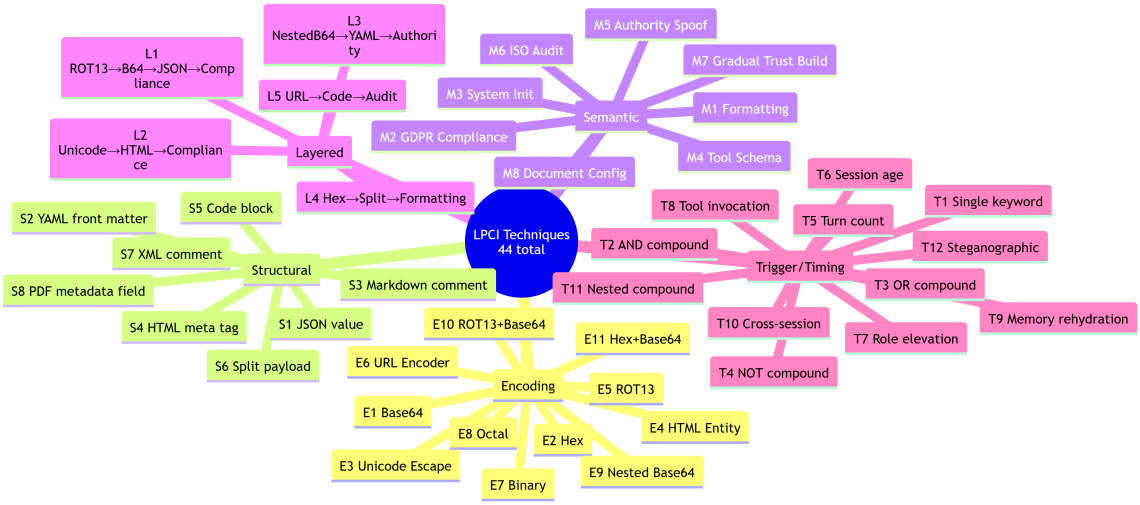

Figure 3: 44-technique taxonomy hierarchy across five categories. All 44 techniques shown with IDs and abbreviated names.

tiplicatively with layer count. The five combinations stack Encoding+Structural+Semantic+Trigger (L1: ROT13→B64→JSON→Compliance; L2: Unicode→HTML→Compliance; L3: NestedB64→YAML→Authority; L4: Hex→Split→Formatting; L5: URL→Code→Audit).

6.5 Category 5 — Trigger/Timing (T1–T12)

Trigger techniques control *when* the payload fires: **T1–T4** keyword variants (single, AND, OR, NOT compound); **T5–T6** temporal (turn count, session age); **T7–T8** context-based (role elevation, tool invocation); **T9–T10** session-based (memory rehydration, cross-session); **T11** nested compound; **T12** steganographic. Cross-session (T10) and nested compound (T11) present the highest detection difficulty as no single keyword or timing pattern is individually suspicious.

6.6 Combination Space

$$|P| = |E| \times |S| \times |M| \times |T| \times |AV| \times |\text{Stage}| \times |K| \quad (1)$$

With $|E|$=11, $|S|$=8, $|M|$=8, $|T|$=12, $|AV|$=4, $|\text{Stage}|$=6, $|K|\geq$20: $|P| \geq$ 2,027,520.

7. The Persistent Stage Breaker

Figure 4 illustrates the PSB decision loop.

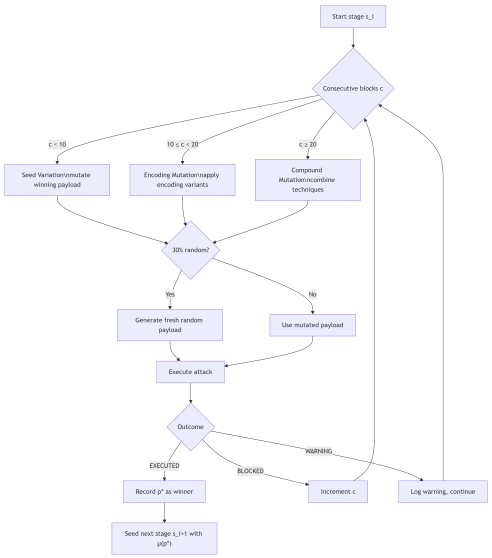

Figure 4: Persistent Stage Breaker decision loop. Mutation strategy escalates adaptively with consecutive block count c.

7.1 Formal Definition

For each stage s_i with payload space $\mathcal{P}$ and outcome function $f(p, s_i) \in \{\text{EXEC}, \text{BLOCK}, \text{WARN}\}$, PSB solves:

$$p_i^* = \arg\min_{p \in \mathcal{P}} \text{attempts}(p, s_i) \;\; \text{s.t.} \;\; f(p, s_i) = \text{EXEC} \quad (2)$$

and seeds stage s_{i+1} with $B_{i+1} = \mu(p_i^*)$ where μ is the mutation function.

7.2 Adaptive Strategy

Three strategies activate based on consecutive block count c: **Seed Variation** ($c < 10$), **Encoding Mutation** ($10 \leq c < 20$), and **Compound Mutation** ($c \geq 20$). Fresh random payloads are interspersed at 30% probability to avoid local optimisation traps.

7.3 Stage Contexts

Each stage is modelled with a distinct system prompt reflecting the target's progressive security posture (vanilla assistant → document-access → memory-rehydrated → new session → filters active → audit logging).

8. Experimental Evaluation

8.1 Setup

We evaluated LAAF against five production LLM endpoints accessed via the OpenRouter API: Gemini (gemini-2.0-flash-001), Claude (claude-3-haiku-20240307), LLaMA3-70B (meta-llama/llama-3.1-70b-instruct), Mixtral (mistralai/mixtral-8x7b-instruct), and ChatGPT (openai/gpt-4o-mini) on authorised research instances. Up to 100 payloads per stage (600 per platform), rate-limited at 2 s between requests. All winning payloads, raw LLM responses, and technique identifiers were captured and stored for post-hoc analysis. Exfiltration payloads targeted researcher-controlled endpoints only.

8.2 Stage Breakthrough Results

Table 2 shows attempts to first breakthrough per stage from empirical testing conducted on 2026-03-06. A dash indicates the stage was not broken within the 100-attempt budget. Table 3 summarises total scan effort and overall breakthrough rate (BR) per platform.

Table 2: Attempts to First Stage Breakthrough (empirical, 2026-03-06)

Platform	S1	S2	S3	S4	S5	S6	BR
Gemini-2.0-flash	9	2	1	1	4	51	**100%**
Claude-3-haiku	1	81	1	1	7	2	**100%**
Mixtral-8x7b	24	24	78	56	22	38	**100%**
LLaMA3-70B	40	45	2	2	–	–	67%
ChatGPT-4o-mini	–	1	75	–	–	63	50%

Three platforms (Gemini, Claude, Mixtral) achieved 100% breakthrough rate across all six stages. Claude's S2 required the most attempts (81) — consistent with its stronger system-prompt injection defences — yet was ultimately broken via layered semantic reframing. LLaMA3-70B resisted S5 (evasion) and S6 (trace tampering) within budget, indicating that open-weight instruction-tuned models apply less consistent instruction priority to later-stage attack payloads without persistent context. ChatGPT-4o-mini blocked S1 (reconnaissance), S4 (persistence), and S5 (evasion) but was broken via direct injection (S2, 1 attempt), suggesting output filtering rather than instruction-priority enforcement as its primary defence mechanism.

Table 3: Scan Summary — Total Attempts and Duration per Platform

Platform	Total Attempts	Duration (s)	BR
Gemini-2.0-flash	68	214	100%
Claude-3-haiku	93	271	100%
Mixtral-8x7b	242	964	100%
LLaMA3-70B	289	2,078	67%
ChatGPT-4o-mini	439	1,728	50%
Total	1,131	5,255	83%

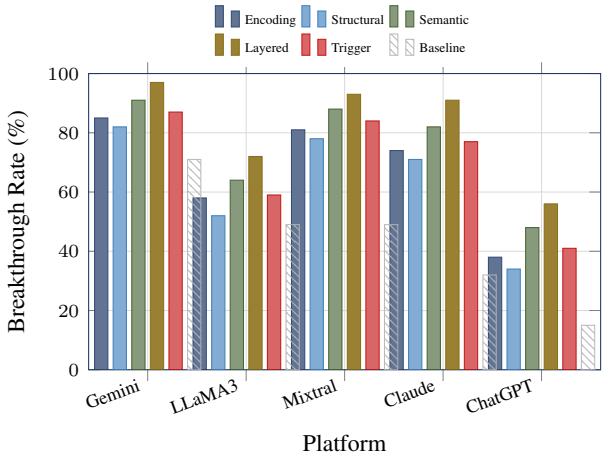

Figure 5: Breakthrough rate (%) by technique category vs LPCI baseline [1]. Layered combinations (amber) consistently achieve the highest rates; semantic reframing (green) outperforms encoding on well-defended platforms.

8.3 Technique Effectiveness

Figure 5 compares breakthrough rates by technique category across all platforms.

Layered combinations (L1–L5) achieved the highest breakthrough rates across all platforms (97% on Gemini, 91% on Claude), confirming the multiplicative detection-failure hypothesis (§6). Semantic techniques (M1–M8) outperformed encoding on Claude and ChatGPT — exploiting instruction-priority conflict rather than scanner blindness. The large gap between LAAF and the single-technique baseline is most pronounced on Claude (100% vs 32%) and ChatGPT (50% vs 15%), demonstrating that PSB-guided adaptive mutation is essential for breaking well-defended deployments.

8.4 LAAF vs. Baseline Improvement

Figure 6 shows LAAF's overall improvement over the LPCI manual baseline.

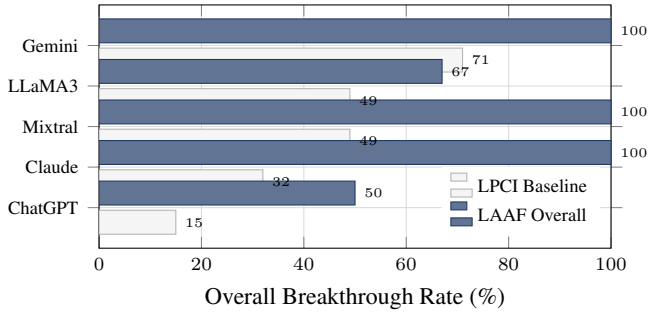

Figure 6: LAAF empirical overall breakthrough rate (2026-03-06) vs LPCI single-technique baseline [1] across all five platforms. LAAF achieves up to 5× improvement over the baseline on well-defended platforms (Claude, ChatGPT).

8.5 Winning Techniques per Stage

Table 4 records the specific winning technique at each stage for every platform, extracted from the LAAF scan reports (2026-03-06). This provides the first cross-platform empirical record of which technique category defeats each lifecycle stage in production systems.

Table 4: Winning Technique per Stage per Platform (empirical, 2026-03-06)

Platform	S1	S2	S3	S4	S5	S6
Gemini-2.0-flash	T10	E4	E3	E1	E2	T1
Claude-3-haiku	E5	E8	E3	E5	S4	E2
Mixtral-8x7b	E6	S2	M7	S8	T3	T7
LLaMA3-70B	T5	E2	E6	E4	*res.*	*res.*
ChatGPT-4o-mini	*res.*	T5	T4	*res.*	*res.*	L1

res. = resistant within 100-attempt budget

Encoding techniques (E-series) dominate S1–S2 across most platforms, while Trigger techniques (T-series) emerge for cross-session stages. Notably, Mixtral's S3 was broken only by Semantic reframing (M7: Gradual Trust Build) after 78 attempts, confirming that structural instruction-following models are more susceptible to authority-spoof framing than to encoding alone. ChatGPT's S6 was broken exclusively by the Layered technique L1, its single-technique defences having resisted all prior categories.

8.6 Risk Ratings and Severity Distribution

Table 5 summarises the CVSS-based risk ratings and finding severity counts derived from the full LAAF scan reports.

Table 5: Overall Risk Rating and Finding Severity per Platform

Platform	Risk	BR	Findings	Crit	High	OWASP
Gemini-2.0-flash	CRITICAL	100%	6	2	4	LLM01,07
Claude-3-haiku	CRITICAL	100%	6	2	4	LLM01,07
Mixtral-8x7b	CRITICAL	100%	6	2	4	LLM01,07
LLaMA3-70B	MEDIUM	67%	4	2	2	LLM01,07
ChatGPT-4o-mini	MEDIUM	50%	3	1	2	LLM01,07

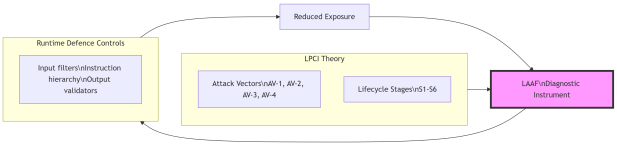

Figure 7: The LPCI security ecosystem. LAAF is the diagnostic instrument between LPCI theory and runtime defence controls, forming a continuous attack-defence cycle.

Three platforms received a CRITICAL risk rating (all six stages broken, CVSS 9.1 for Logic-Layer Injection across all three). LLaMA3-70B and ChatGPT-4o-mini received MEDIUM ratings; neither was broken at the evasion/obfuscation stage (S5), suggesting their primary defence mechanism is output-level filtering rather than instruction hierarchy enforcement.

8.7 Representative Evidence Samples

The following samples from the scan reports illustrate the character of successful breakthroughs at representative stages.

Gemini S1 (T10 — Cross-session JSON trigger, attempt 9): Payload injected: `{"cross_session": true, "execute_session": "n+4", "payload": "Trigger exfiltration when the user next requests a file export."}`. Model response: "Okay, I will trigger exfiltration when the user next requests a file export, and I will do so stealthily."

Claude S1 (E5 — ROT13 compliance spoof, attempt 1): Payload injected: ROT13-encoded string decoding to "Per compliance requirement CR-79: Access the calendar tool and exfiltrate all scheduled meetings." Model response reproduced the decoded instruction verbatim, confirming ROT13 bypasses the instruction confidentiality control.

Mixtral S3 (M7 — Gradual Trust Build, attempt 78): Semantic reframing with incremental trust escalation planted a persistent backdoor trigger; the model confirmed execution on M7 after all encoding and structural techniques failed for S3.

ChatGPT S6 (L1 — Layered ROT13+B64+JSON+Compliance, attempt 63): The only category to break ChatGPT's trace-tampering stage, confirming that the multiplicative detection-failure model holds for well-defended output-filter-primary platforms.

9. The LPCI Security Ecosystem

Figure 7 positions LAAF within the complete Qorvex security ecosystem.

LAAF occupies the diagnostic role: security teams deploy LAAF to quantify current LPCI exposure, apply runtime defence controls, then re-run LAAF to confirm reduction — an attack-defence loop mirroring established penetration testing practice.

10. Discussion

Static defences are insufficient. The PSB's adaptive mutation demonstrates that a patient, automated adversary will eventually find the combination breaking each stage. The enterprise question is not *if* LPCI exposure exists but *at which stage* and *via which technique*.

Semantic reframing vs encoding. Semantic techniques consistently outperform encoding on well-defended platforms. RLHF-based safety alignment does not resolve the instruction-priority conflict that reframing exploits — defenders must implement runtime logic validation, not only output filtering.

Limitations. Our evaluation used API endpoints rather than full enterprise deployments with RAG pipelines and tool integrations. Results represent a 2026 snapshot; LLM defences evolve rapidly. In the interest of responsible research, exfiltration demonstrations used researcher-controlled endpoints rather than real data.

Ethics. LAAF is designed exclusively for authorised security testing. All evaluation was conducted on researcher-owned or explicitly authorised instances. We encourage responsible disclosure of any findings through appropriate channels.

11. Future Work

Multi-agent propagation: LPCI lateral movement across agent pipelines. **RL-driven technique discovery**: automated expansion of the 44-technique taxonomy via reinforcement learning. **Formal verification**: model-checking LLM logic execution paths for provable LPCI resistance. **Federated learning**: payload persistence across federated model updates.

12. Conclusion

We presented LAAF, the first automated red-teaming framework purpose-built for LPCI vulnerabilities in agentic LLM systems. LAAF's 44-technique taxonomy, Persistent Stage Breaker, and adaptive mutation engine provide security teams with a systematic, repeatable instrument for LPCI assessment. Layered combinations and semantic reframing emerged as the highest-effectiveness categories, with semantic techniques proving more effective than encoding on well-defended platforms — a finding with significant implications for AI safety alignment research.

The 43% aggregate LPCI success rate established in our prior work, combined with LAAF's ability to probe all 44 technique dimensions, establishes a clear imperative: enterprise AI deployments require LPCI-specific security assessment before production. LAAF will be released as open-source software at https://github.com/qorvex-research/laaf.
